# Introduction

These notes are based on my lectures for the course Multigrid Methods (NMNV571) at the Faculty of Mathematics and Physics, Charles University. As lecture notes, they are still a work in progress, with the goal of continuously improving the presentation of the material for students.

The course content is currently divided into three parts:

1. A thorough introduction to multigrid and its key principles (following [Briggs et al., 2000]),
2. An abstract formulation of multigrid, including convergence results and sufficient conditions for convergence (adapted from [Shaidurov, 1995]),
3. Stable splitting as an advanced topic (following [Rüde, 1993]).

The third part may be adjusted based on students' preferences. For instance, topics such as algebraic multigrid or multigrid for nonlinear problems could be considered.

As of February 2025, my aim is to cover at least the first two topics in these notes.

# Chapter 1

## Key principles of the multigrid

We begin with a detailed and gradual introduction to the key principles of multigrid. For clarity, we illustrate these concepts using a simple model problem—a Poisson equation on a basic domain—discretized with finite differences.

Our presentation follows [Briggs et al., 2000], where additional details and numerical experiments can be found. However, there is a key distinction: in much of the literature (including [Briggs et al., 2000]), multigrid is often described as an enhancement of stationary iterative methods. I find this perspective overly simplistic and somewhat misleading. Instead, we present multigrid as the combination of two complementary techniques that together yield a truly efficient solver or preconditioner.

### 1.1 Error, Residual, Iterative Refinement

Consider solving

$$Au = f,$$

where  $A$  is a non-singular matrix,  $f$  is the right-hand side, and  $u$  is the exact solution. We will denote an approximate solution either by  $v$  (if it is arbitrary) or by  $u^{(i)}$  (if we want to emphasize an iterative procedure).

**Error** or the *algebraic error*, is the key vector,  $e = u - v$ , or  $e^{(i)} = u - u^{(i)}$ . Given an approximation  $v$  with the error  $e$ , we have

$$v + e = v + u - v = u,$$

so that we can compute the exact solution.

**Residual** is the computable vector given by  $r = f - Av$ , or  $r^{(i)} = f - Au^{(i)}$ . There holds

$$r = f - Av = Au - Av = A(u - v) = Ae.$$

From  $\mathbf{e} = \mathbf{A}^{-1}\mathbf{r}$  and  $\mathbf{f} = \mathbf{A}\mathbf{u}$  we have

$$\|\mathbf{e}\| \leq \|\mathbf{A}^{-1}\| \|\mathbf{r}\|, \quad \|\mathbf{f}\| \leq \|\mathbf{A}\| \|\mathbf{u}\|$$

and altogether

$$\frac{\|\mathbf{e}\|}{\|\mathbf{u}\|} \leq \frac{\|\mathbf{A}\| \|\mathbf{A}^{-1}\| \|\mathbf{r}\|}{\|\mathbf{f}\|} = \kappa(\mathbf{A}) \frac{\|\mathbf{r}\|}{\|\mathbf{f}\|},$$

where  $\kappa(\mathbf{A}) = \|\mathbf{A}\| \|\mathbf{A}^{-1}\|$  is the condition number of  $\mathbf{A}$ . Therefore  $\mathbf{r} = 0$  if and only if  $\mathbf{v} = \mathbf{u}$  but a small residual norm need not guarantee a small norm of the error if  $\kappa(\mathbf{A})$  is not small.

**Iterative refinement** is the following procedure for a given approximation  $\mathbf{u}^{(i)}$

1. Compute the residual  $\mathbf{r}^{(i)} = \mathbf{f} - \mathbf{A}\mathbf{u}^{(i)}$ .
2. Solve  $\mathbf{A}\mathbf{e}^{(i)} = \mathbf{r}^{(i)}$  approximately, giving  $\mathbf{d}^{(i)}$ .
3. Define a new approximation  $\mathbf{u}^{(i+1)} = \mathbf{u}^{(i)} + \mathbf{d}^{(i)}$ .

If the solution in 2. can be written as

$$\mathbf{d}^{(i)} = \mathbf{M}^{-1}\mathbf{r}^{(i)},$$

with some  $\mathbf{M} \approx \mathbf{A}$ , then

$$\mathbf{u}^{(i+1)} = \mathbf{u}^{(i)} + \mathbf{M}^{-1}\mathbf{r}^{(i)} = \mathbf{u}^{(i)} + \mathbf{M}^{-1}(\mathbf{f} - \mathbf{A}\mathbf{u}^{(i)})$$

and for the error it holds

$$\mathbf{e}^{(i+1)} = \mathbf{u} - \mathbf{u}^{(i+1)} = \mathbf{u} - \mathbf{u}^{(i)} - \mathbf{M}^{-1}(\mathbf{f} - \mathbf{A}\mathbf{u}^{(i)}) = (\mathbf{I} - \mathbf{M}^{-1}\mathbf{A})\mathbf{e}^{(i)},$$

where  $\mathbf{I}$  denotes the identity matrix (of the proper size).

If  $\mathbf{M}$  is independent of  $i$ ,  $\mathbf{u}^{(i)}$ ,  $\mathbf{r}^{(i)}$ , the above iterative scheme is called *linear* or *stationary*. Examples of such schemes are Jacobi, Gauss–Seidel, SOR or Richardson methods.

There are also nonlinear iterative methods, for example Krylov subspace methods. Nevertheless, in (standard) preconditioned Krylov methods, a preconditioned residual is computed as  $\mathbf{z}^{(i)} = \mathbf{M}^{-1}\mathbf{r}^{(i)}$  in each iteration.

## 1.2 Model Problem and its Discretization

Consider the homogeneous Poisson problem

$$-\Delta u = f \quad \text{in } \Omega = (0, 1)^d, \quad (1.1)$$

$$u = 0 \quad \text{on } \partial\Omega. \quad (1.2)$$

We will often consider  $d = 1$  for illustrations and  $d = 2$  for computations. The true power of multigrid (and multilevel methods in general) comes, in particular, with 3D problems.

The boundary conditions (1.2) can be generalized as well as reaction term  $\sigma u$  can be added to the left-hand side of (1.1). The domain can be more complex but not too much; this often remains one of the limitations for an efficient (geometric) multigrid.

Figure 1.1: Uniform partitioning in 1D

### 1.2.1 Discretization in 1D

Consider the uniform partitioning of the interval  $(0, 1)$  with  $n$  intervals and  $n + 1$  nodes

$$x_j = jh = j/n, \quad j = 0, 1, \dots, n.$$

Denote by  $v_j$  an approximation to value of the exact solution  $u$  in the node  $x_j$ ,  $v_j \approx u(x_j)$  and consider the vector of unknowns

$$\mathbf{v} = [v_1, v_2, \dots, v_{n-1}]^T.$$

We replace the second derivative  $u''$  in (1.1) by the central difference,

$$-u''(x_j) \approx \frac{-u(x_{j-1}) + 2u(x_j) - u(x_{j+1}))}{h^2},$$

giving the system of linear equations

$$\begin{aligned} v_0 = v_n = 0, \\ \frac{-v_{j-1} + 2v_j - v_{j+1}}{h^2} = f(x_j) \quad j = 1, 2, \dots, n-1. \end{aligned} \quad (1.3)$$

When denoting  $f_j = f(x_j)$ ,  $j = 1, \dots, n-1$  and  $\mathbf{f} = [f_1, \dots, f_{n-1}]^T$ , we can write the matrix form of (1.3)

$$\frac{1}{h^2} \begin{bmatrix} 2 & -1 & & & \\ -1 & 2 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & & -1 & 2 \end{bmatrix} \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_{n-1} \end{bmatrix} = \begin{bmatrix} f_1 + h^{-2}v_0 \\ f_2 \\ \vdots \\ f_{n-1} + h^{-2}v_n \end{bmatrix}. \quad (1.4)$$

### 1.2.2 Discretization in 2D

Consider the uniform partitioning of the interval  $(0, 1)$  with  $m + 1$  nodes

$$x_i = ih_x = i/m, \quad i = 0, 1, \dots, m.$$

and  $n + 1$  nodes for the  $y$ -direction

$$y_j = jh_y = j/n, \quad j = 0, 1, \dots, n.$$

Figure 1.2: 2D partitioning with illustration of values for 2D central differences

This gives us  $(m + 1) \times (n + 1)$  nodes of the mesh  $(x_i, y_j)$ ,  $i = 0, 1, \dots, m$ ,  $j = 0, 1, \dots, n$ . Denote by  $v_{i,j}$  an approximation to value of the exact solution  $u$  in the node  $(x_i, y_j)$ ,

$$v_{i,j} \approx u(x_i, y_j), \quad i = 0, 1, \dots, m, \quad j = 0, 1, \dots, n.$$

Recall, that the model problem (1.1) in 2D reads

$$-\Delta u = -\frac{\partial^2}{\partial x^2} u - \frac{\partial^2}{\partial y^2} u = f.$$

Replacing the second derivatives  $\partial^2 u / \partial x^2$  and  $\partial^2 u / \partial y^2$  by central differences, as in 1D, gives

$$\frac{-v_{i-1,j} + 2v_{i,j} - v_{i+1,j}}{h_x^2} + \frac{-v_{i,j-1} + 2v_{i,j} - v_{i,j+1}}{h_y^2} = f_{i,j} = f(x_i, y_j), \quad 1 \leq i \leq m-1, \quad 1 \leq j \leq n-1, \quad (1.5)$$

with homogeneous boundary conditions represented by

$$v_{0,j} = v_{m,j} = v_{i,0} = v_{i,n} = 0, \quad 0 \leq i \leq m, \quad 0 \leq j \leq n. \quad (1.6)$$

The system has  $(m - 1) \times (n - 1)$  unknowns that can be written into a vector “row-” or “column-wise”. We will consider the later one. Denote

$$\begin{aligned} \mathbf{v}_i &= [v_{i,1}, v_{i,2}, \dots, v_{i,n-1}]^T \\ \mathbf{f}_i &= [f_{i,1}, f_{i,2}, \dots, f_{i,n-1}]^T, \quad 1 \leq i \leq m-1, \end{aligned}$$

and write (1.5) (now already with boundary conditions (1.6)) as

$$\begin{bmatrix} \mathbf{B} & -al & & \\ -al & \mathbf{B} & -al & \\ & \ddots & \ddots & \ddots \\ & & -al & \mathbf{B} \end{bmatrix} \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \\ \vdots \\ \mathbf{v}_{n-1} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_1 \\ \mathbf{f}_2 \\ \vdots \\ \mathbf{f}_{n-1} \end{bmatrix}. \quad (1.7)$$

We assume that  $N_0 \ll N_1$ .

Given an approximation  $\mathbf{u}_1^{(i)}$  to the solution  $\mathbf{u}_1$  of the fine-level problem  $\mathbf{A}_1 \mathbf{u}_1 = \mathbf{f}_1$ , compute the associated residual  $\mathbf{r}_1^{(i)} = \mathbf{f}_1 - \mathbf{A}_1 \mathbf{u}_1^{(i)}$ . The idea of the *coarse-space correction* is to solve the problem with  $\mathbf{A}_0$  (corresponding to the coarse level) and this use to improve (correct) the approximation  $\mathbf{u}_1^{(i)}$  on the fine level. Therefore, we solve

$$\mathbf{A}_0 \mathbf{d}_0^{(i)} = \mathbf{R}_1^0 \mathbf{r}_1^{(i)} \quad (1.8)$$

and hope that

$$\mathbf{l}_0^1 \mathbf{d}_0^{(i)} \approx \mathbf{e}_1^{(i)} = \mathbf{u}_1 - \mathbf{u}_1^{(i)}.$$

In the notation from the previous section,

$$\mathbf{u}_1^{(i+1)} = \mathbf{u}_1^{(i)} + \mathbf{l}_0^1 (\mathbf{A}_0)^{-1} \mathbf{R}_1^0 \mathbf{r}_1^{(i)}.$$

The analysis of multigrid methods typically assumes that (1.8) is solved exactly. We will also stick with this assumption for (most of) the course.

Natural and key question arises, when does the coarse-space correction work? Vaguely, we need the problem  $\mathbf{A}_0 \mathbf{d}_0^{(i)} = \mathbf{R}_1^0 \mathbf{r}_1^{(i)}$  to be close to  $\mathbf{A}_1 \mathbf{d}_1^{(i)} = \mathbf{r}_1^{(i)}$ , to capture “all its important features”. Algebraically, the matrices  $\mathbf{l}_0^1$  and  $\mathbf{R}_1^0$  are rectangular so that they have (nontrivial) ranges and kernels. Then

- the norm  $\|\mathbf{l}_0^1 \mathbf{d}_0^{(i)} - \mathbf{e}_1^{(i)}\|$  can only be (relatively) small, if  $\mathbf{e}_1^{(i)}$  is close to  $Im(\mathbf{l}_0^1)$ , the range of  $\mathbf{l}_0^1$ ,
- $\mathbf{R}_1^0 \mathbf{r}_1^{(i)}$  (nearly) vanishes if  $\mathbf{r}_1^{(i)}$  is close to  $Ker(\mathbf{R}_1^0)$ , the kernel of  $\mathbf{R}_1^0$ .

These loosely formulated observations motivate our following development on how to complement the coarse-space correction to develop a truly efficient solver. Later, in the convergence analysis, we will see rigorous formulations.

### 1.3.2 Interpolation and restriction for finite differences

#### 1D

Given a fine grid (partitioning) with the step size  $h_1 = 1/n$ , it is natural to consider the coarse grid as “every second node”, i.e., a partitioning with  $h_0 = 2h_1$ . Since the value in the boundary nodes is determined by the boundary condition (equal to zero), for the number of degrees of freedom, internal nodes, we have  $N_1 = 2N_0 - 1$ .

analysis because of preserving the symmetry. Moreover, if<sup>2</sup>

$$A_0 = R_1^0 A_1 l_0^1,$$

then for the coarse-space correction we have

$$\begin{aligned} \mathbf{u}^{(i+1)} &= \mathbf{u}^{(i)} + l_0^1 (R_1^0 A_1 l_0^1)^{-1} R_1^0 \mathbf{r}^{(i)}, \\ \mathbf{e}^{(i+1)} &= (I - l_0^1 (R_1^0 A_1 l_0^1)^{-1} R_1^0 A_1) \mathbf{e}^{(i)}, \end{aligned}$$

where  $(I - l_0^1 (R_1^0 A_1 l_0^1)^{-1} R_1^0 A_1)$  is a projection (i.e.,  $P = P^2$ ).

## 2D

There are more choices of coarse degrees of freedom possible in 2D. The most popular that reduces the number of DOFs by factor of 4 while assuring that every fine-level node has two coarse nodes “nearby” is

For the ease of presentation, we did not display the boundary nodes.

The *interpolation* can be represented by a so-called stencil, describing how the value in the coarse DOF is “spread” to the neighboring fine nodes. A natural one is

$$\begin{pmatrix} 1/4 & 1/2 & 1/4 \\ 1/2 & 1 & 1/2 \\ 1/4 & 1/2 & 1/4 \end{pmatrix}, \quad \text{graphically} \quad \begin{array}{ccc} \bullet & \bullet & \bullet \\ \bullet & \text{coarse node} & \bullet \\ \bullet & \bullet & \bullet \end{array}$$

$1 \times$  (curved arrow from coarse node to itself)  
 $\frac{1}{2} \times$  (downward arrow from coarse node to node below)  
 $\frac{1}{4} \times$  (diagonal arrow from coarse node to node at bottom-left)

Please note that the stencil is not a submatrix of the interpolation matrix. The values from the stencil are on a proper positions in a (sparse) column vector of the interpolation matrix.

The full-weightening *restriction* in 2D, given as the analogy to 1D case above, is as follows

<sup>2</sup>This happens for example for the matrices from finite element discretizations.

This gives, for the restriction matrix,

$$R_1^0 = \frac{1}{4}(\mathbf{l}_0^1)^T = \left(\frac{1}{2}\right)^d (\mathbf{l}_0^1)^T.$$

### 1.3.3 Stationary iterative methods and smoothing property

Stationary iterative methods is a class of methods based on matrix splitting. Let

$$A = D - L - U, \tag{1.9}$$

where  $D$  is the diagonal of  $A$ ,  $-L$  is its strictly lower part, and  $U$  is the strictly upper part of  $A$ .

**Jacobi Method** is based on the relationship

$$A\mathbf{u} = \mathbf{f} = D\mathbf{u} - (L + U)\mathbf{u} \quad \Rightarrow \quad \mathbf{u} = D^{-1}(L + U)\mathbf{u} + D^{-1}\mathbf{f}$$

giving the iterative scheme

$$\mathbf{u}^{(i+1)} = R_J \mathbf{u}^{(i)} + D^{-1}\mathbf{f}, \quad R_J = D^{-1}(L + U). \tag{1.10}$$

**Weighted (damped) Jacobi Method** is a variant of Jacobi method where the new approximation is given as a linear combination of the previous approximation and the vector given by the (standard) Jacobi. For some  $\omega \in \mathbb{R}$ ,

$$\begin{aligned} \mathbf{u}^{(i+1)} &= \omega(R_J \mathbf{u}^{(i)} + D^{-1}\mathbf{f}) + (1 - \omega)\mathbf{u}^{(i)} = R_\omega \mathbf{u}^{(i)} + \omega D^{-1}\mathbf{f}, \\ R_\omega &= \omega R_J + (1 - \omega)I = I - \omega D^{-1}A. \end{aligned} \tag{1.11}$$

With  $\omega = 1$ ,  $R_\omega = R_J$  and the weighted Jacobi becomes the standard Jacobi method.

The practical disadvantage of both the method is that they requires storing both  $\mathbf{u}^{(i)}$  and  $\mathbf{u}^{(i+1)}$ . In some applications, it is not possible to store more than a single solution vector. It may be then useful, if the vector  $\mathbf{u}^{(i)}$  is overwritten in the computation.

**Gauss–Seidel Method** is based on

$$(D - L)\mathbf{u} = U\mathbf{u} + \mathbf{f} \quad \Rightarrow \quad \mathbf{u} = (D - L)^{-1}U\mathbf{u} + (D - L)^{-1}\mathbf{f}$$

giving the iterative scheme

$$\mathbf{u}^{(i+1)} = R_{GS} \mathbf{u}^{(i)} + (D - L)^{-1}\mathbf{f}, \quad R_{GS} = (D - L)^{-1}U. \tag{1.12}$$

The implementation of Gauss–Seidel allows to store only one approximate vector and update consecutively its components. Then, in contrast to Jacobi methods, the ordering of degrees of freedom may affect the behavior of the solver.

Figure 1.3: Splitting the nodes for red-black Gauss–Seidel in 1D and 2D

**Red-black Gauss–Seidel Method** is a variant of GS to enhance its parallelization. The idea is to split the degrees of freedom into two groups (“red” and “black”) as in Figure 1.3.

The advantage of such splitting is that the “red” values are updated using the neighboring “black” values and vice versa. Instead of updating the elements of the vector  $\mathbf{u}^{(i+1)}$  one by one, we can do the update in two steps; update first all the values in one of the groups and then update the second one.

There are also other stationary methods (for example Richardson method, Successive over-relaxation method (SOR), Symmetric successive over-relaxation (SSOR)) that we do not discuss in detail.

### Smoothing property

For an iterative process

$$\mathbf{u}^{(i+1)} = \mathbf{R}\mathbf{u}^{(i)} + \mathbf{g},$$

satisfying  $\mathbf{u} = \mathbf{R}\mathbf{u} + \mathbf{g}$  (i.e. such that  $\mathbf{u}$  is its fixed point), the two consecutive errors satisfy

$$\mathbf{e}^{(i+1)} = \mathbf{R}\mathbf{e}^{(i)}. \tag{1.13}$$

Recursively

$$\mathbf{e}^{(i+1)} = \mathbf{R}^{i+1}\mathbf{e}^{(0)}. \tag{1.14}$$

We saw an analogous relation for iterative refinement with  $\mathbf{R} = \mathbf{I} - \mathbf{M}^{-1}\mathbf{A}$ .

From the elementary course on numerical analysis,

$$\lim_{i \rightarrow \infty} \mathbf{R}^i = \mathbf{0} \iff \rho(\mathbf{R}) < 1,$$

where  $\rho(\cdot)$  is the spectral radius. In other words,  $\mathbf{R}^i$  tends to zero iff  $|\lambda| < 1$  for each  $\lambda$  from the spectrum of  $\mathbf{R}$ .

Let  $(\lambda, \mathbf{v})$  be the eigenpair of  $\mathbf{R}$ . Then

$$\mathbf{R}^i \mathbf{v} = \mathbf{R}^{i-1} \mathbf{R} \mathbf{v} = \lambda \mathbf{R}^{i-1} \mathbf{v} = \dots = \lambda^i \mathbf{v}$$

and  $\|\mathbf{R}^i \mathbf{v}\| = |\lambda|^i \|\mathbf{v}\|$ . Therefore  $\|\mathbf{R}^i \mathbf{v}\| / \|\mathbf{v}\|$  converges to 0 faster for  $|\lambda|$  small (closer to 0) and converges slower for  $|\lambda|$  large (closer to 1).

When decomposing  $\mathbf{e}^{(i)}$  into the eigensubspaces of  $\mathbf{R}$ , some components will decay more rapidly as  $i \rightarrow \infty$ , while others will persist longer.

In applications, the eigenvectors of  $\mathbf{R}$  associated with small eigenvalues (in the magnitude) are typically oscillating and those associated with large eigenvalues are smooth. Therefore

$$\mathbf{e}^{(i)} = \mathbf{R}^i \mathbf{e}^{(0)} \quad \text{is for large } i \text{ a smooth vector.}$$

This is therefore called a *smoothing property (of stationary methods)*.

The smoothing property has two important consequences:

- The error will be after few steps dominated by the eigenvectors associated with large eigenvalues of  $\mathbf{R}$  (that are smooth).
- For appropriate starting vectors, smoothers (stationary iterative methods) converge fast. Such vectors are dominated by the eigenvectors associated with the smallest eigenvalues of  $\mathbf{R}$ .

It is however more practical to relate smoothness to the problem to be solved and not to a particular method. For  $(\lambda_k, \mathbf{v}_k)$  an eigenpair of  $\mathbf{A}$ , there holds

$$\|\mathbf{v}_k\|_{\mathbf{A}}^2 = \mathbf{v}_k^T \mathbf{A} \mathbf{v}_k = \mathbf{v}_k^T \lambda_k \mathbf{v}_k = \lambda_k \|\mathbf{v}_k\|^2.$$

For model Poisson problem, the  $\mathbf{A}$  norm corresponds to an energy that is minimized by the exact solution  $u$ . Then it is said that a *smooth* vector has small energy, while an *oscillating* vector has high energy. Therefore smooth eigenvectors are those corresponding to small eigenvalues while oscillating eigenvectors to the large ones.

Since  $\mathbf{A}$  is diagonalizable, there exists an orthonormal basis of  $\mathbb{R}^N$  formed from its eigenvectors. We can then focus on how the smoothing (application of a stationary iterative method) and coarse-space correction act on the eigenvectors of  $\mathbf{A}$ .

### **Eigenpairs of 1D finite-difference matrices and smoothing property for (weighted) Jacobi**

Recall

$$\mathbf{R}_\omega = \omega \mathbf{R}_J + (1 - \omega) \mathbf{I} = \mathbf{I} - \omega \mathbf{D}^{-1} \mathbf{A}.$$

For  $\mathbf{A}$  from (1.4),  $\mathbf{D} = 2\mathbf{I}$  and therefore<sup>3</sup>

$$\mathbf{D}^{-1} = \frac{1}{2} \mathbf{I}, \quad \mathbf{R}_\omega = \mathbf{I} - \frac{\omega}{2} \mathbf{A}.$$

From this one can see that for  $(\lambda_k, \mathbf{v}_k)$  an eigenpair of  $\mathbf{A}$ ,  $\mathbf{v}_k$  is also an eigenvector of  $\mathbf{R}_\omega$  and

$$\mathbf{R}_\omega \mathbf{v}_k = \left(1 - \frac{\omega}{2} \lambda_k\right) \mathbf{v}_k.$$

---

<sup>3</sup>In 2D and 3D,  $\mathbf{D} = \alpha \mathbf{I}$  for some  $\alpha$  so that analogous result holds too.

**Exercise.** Verify by computation that for  $\mathbf{A}$  from (1.4) of order  $n$ , the eigenpairs are

$$\lambda_k(\mathbf{A}) = 4 \sin^2 \left( \frac{k\pi}{2n} \right), \quad 1 \leq k \leq n-1, \quad (1.15)$$

$$\mathbf{v}_{k,j} = \sin \left( \frac{jk\pi}{n} \right) \quad 1 \leq k \leq n-1, 1 \leq j \leq n-1. \quad (1.16)$$

Using (1.15), the eigenvalues of  $\mathbf{R}_\omega$  are

$$\lambda_k(\mathbf{R}_\omega) = 1 - 2\omega \sin^2 \left( \frac{k\pi}{2n} \right), \quad 1 \leq k \leq n-1. \quad (1.17)$$

Note that with a finer partitioning,  $n$  increases, leading to the spectrum of  $\mathbf{R}_\omega$  approaching one, which generally slows down the convergence of the method.

We now illustrate the above findings in experiments. First, we plot in Figure 1.4, left, the function

$$\lambda(x) = 1 - 2\omega \sin^2 \left( \frac{x\pi}{2n} \right), \quad x \in (0, n), \quad (1.18)$$

here with  $n = 64$  and several choices of  $\omega$ . Namely,  $\omega = \frac{1}{3}, \frac{1}{2}, \frac{2}{3}$ , and 1. Please note that the choice of  $n$  does not play a role here; it is only important to define the smallest eigenvalue in (1.17) corresponding to  $x = 1$ . From the figure we can identify the modes (given by integer values of  $x$ ) where the absolute value of the function  $\lambda$  is the smallest, which indicate that the damped Jacobi is reducing these modes the most efficiently. For (standard) Jacobi, this is around  $x = n/2$ , for a damped variant, this  $x$  increases; for example, it equals to  $n$  for  $\omega = 1/2$ .

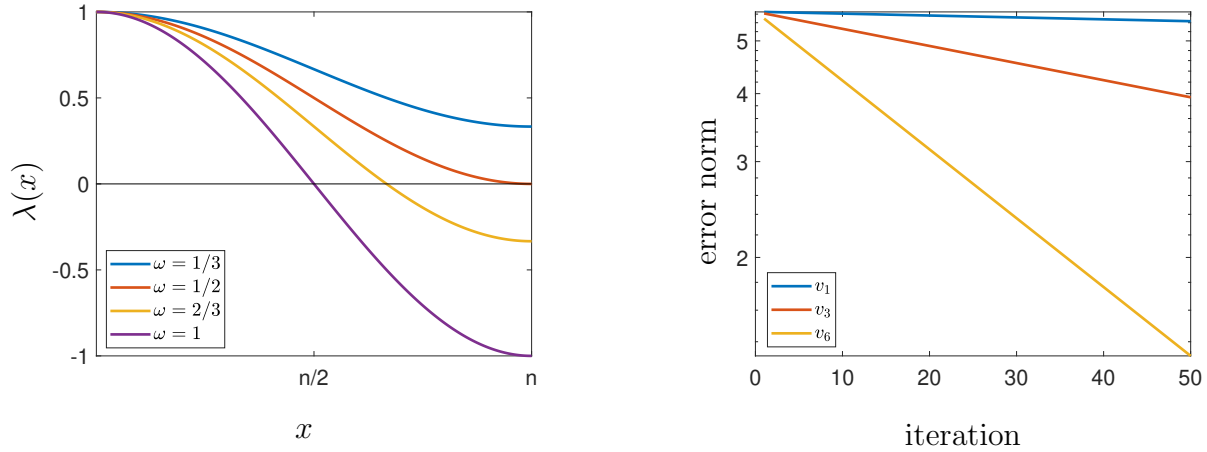

Figure 1.4: Function (1.18) describing the spectrum of  $\mathbf{R}_\omega$  in 1D (left). Euclidean norm of the error in the iterations of weighted Jacobi with  $\omega = 2/3$  when the initial error is equal to  $\mathbf{v}_1$ ,  $\mathbf{v}_3$ , respectively  $\mathbf{v}_6$  (right).

Varying convergence speed for different eigenvectors from (1.16) is illustrated in the right part of Figure 1.4, where the euclidean norm of the error  $\|\mathbf{e}^{(i)}\|$  is plot. Therein, we set

$n = 64$ , and solve the problem  $Au = 0$  by damped Jacobi with  $\omega = 2/3$  and starting with  $\mathbf{v}_k$  with  $k = 1, 3, 6$ . This choice of the problem and the initial guess means that the initial error is equal to  $\mathbf{v}_k$ . We clearly see that the error corresponding to a smaller  $k$  is reduced significantly less efficiently.

Finally, we plot the contraction of the error

$$\frac{\|\mathbf{e}^{(5)}\|}{\|\mathbf{e}^{(0)}\|} \tag{1.19}$$

in 5 iterations of (damped) Jacobi, together with the number of iterations needed to reduce the euclidean norm of the error  $\|\mathbf{e}^{(i)}\|$  by two order of magnitude for the initial error equal to  $\mathbf{v}_k$ ,  $k = 1, \dots, n$ ,  $n = 64$ . For the ease of presentation, the  $y$ -axis is cut at 100; in fact, more than 5700 iterations are needed for  $k = 1$  and damped Jacobi. In Figure 1.5, we give the results for Jacobi method and in Figure 1.6 for the damped Jacobi with  $\omega = 2/3$ . One can see that Jacobi method has difficulties to reduce the error in the subspaces corresponding to the eigenvectors with small and large  $k$ . The damped Jacobi handles better eigenvectors with large  $k$  but still fails for those with  $k$  small. These are low oscillating vectors; cf. (1.15).

Figure 1.5: Jacobi method: contraction factor (1.19) (left) and the number of iterations needed to reduce the euclidean norm of the error by 100 (right). The initial error is given by the eigenvectors  $\mathbf{v}_k$  from (1.16). For small and large indices the number of iterations exceeds 100.

### Gauss–Seidel method

For Gauss–Seidel, in general, the eigenvectors of  $A$  are not the eigenvectors of  $R_{GS}$ . Therefore the analysis of smoothing property is more subtle and we only illustrate it below in Figure 1.7.

Figure 1.6: Damped Jacobi method with  $\omega = 2/3$ : contraction factor (1.19) (left) and the number of iterations needed to reduce the euclidean norm of the error by 100 (right). The initial error is given by the eigenvectors  $\mathbf{v}_k$  from (1.16).

Figure 1.7: Gauss–Seidel method: Euclidean norm of the error when the initial error is equal to  $\mathbf{v}_1$ ,  $\mathbf{v}_3$ , respectively  $\mathbf{v}_6$  (left). Number of iterations needed to reduce the euclidean norm of the error by 100; the initial error is given by the eigenvectors  $\mathbf{v}_k$  from (1.16) (right).

## 1.4 Multigrid Method

The multigrid solver (or preconditioner) efficiently combines smoothing and coarse-space correction. In a two-level setting, we can consider three variants:

**Var. I:** start with smoothing and correct a smooth error on the coarse level

**Var. II:** perform the coarse-space correction, giving an oscillating error that is then smoothed out

**Var. III:** combine **I.** (*pre-smoothing*) and **II.** (*post-smoothing*)

The latter variant can be illustrated by the scheme as

Generalization to a hierarchy of grids is based on the idea not to solve the problem in the coarse-space correction by a direct solver (mathematically by inverting the matrix), but to use a recursion until the coarsest-level problem is small enough.

The basic multigrid scheme is called *V-cycle* and can be illustrated as

The recursive call can be more complex, giving, for example *W-cycle*

We will later see a rigorous algorithmic description of both V- and W-cycles.

Finally, we illustrate a FMG (full multigrid) that can be regarded as a non-iterative procedure, which starts on the coarsest level

**Exercise.** Write a pseudocode for the three MG variants described above. What additional functions does FMG require beyond those used in V- or W-cycles?

# Chapter 2

## Abstract formulation of a multigrid and its convergence

In this section, we present a general, abstract formulation of multigrid, derive an operator that describes error reduction, and establish several sufficient conditions for the convergence of the multigrid solver. This presentation closely follows [Shaidurov, 1995, Section 4].

### 2.1 An abstract multigrid algorithm

Consider

- a sequence of finite-dimensional spaces

$$M_0, M_1, \dots, M_k$$

with the inner products  $(\cdot, \cdot)_i$  on  $M_i$ ,  $i = 0, 1, \dots, k$ ,

- interpolation operators

$$I_i^{i+1} : M_i \rightarrow M_{i+1}, \quad i = 0, 1, \dots, k-1,$$

- restriction operators

$$R_{i-1}^i : M_i \rightarrow M_{i-1}, \quad i = 1, 2, \dots, k,$$

- invertible operators

$$A_i : M_i \rightarrow M_i, \quad i = 0, 1, \dots, k,$$

- smoothers

$$D_{i,\ell}^{PRE}, D_{i,j}^{POST} : M_i \rightarrow M_i, \quad i = 1, 2, \dots, k, \quad \ell = 1, 2, \dots, m_1, \quad j = 1, 2, \dots, m_2.$$

Given  $f_k \in m_k$ , we seek  $u_k \in M_k$  such that

$$A_k u_k = f_k.$$

We define  $MG_i$ -algorithm for solving auxiliary problems  $A_i v_i = g_i$  for arbitrary right-hand side  $g_i$  and an initial approximation  $w_i^{(0)}$ .

**$MG_i$ -algorithm**  $w_i^{(1)} = MG_i(w_i^{(0)}, g_i)$

If  $i = 0$ ,  $w_i^{(1)} = A_0^{-1} g_i$  and leave, otherwise

(A1) presmoothing: set  $v^{(0)} = w_i^{(0)}$  and

$$v^{(\ell)} = v^{(\ell-1)} + D_{i,\ell}^{PRE}(g_i - A_i v^{(\ell-1)}), \quad \ell = 1, 2, \dots, m_1.$$

(A2) restriction:

$$g_{i-1} = R_{i-1}^i (g_i - A_i v^{(m_1)}),$$

(A3) coarse-space solution: set  $\tilde{w}^{(0)} = 0$  and call  $\gamma$ -times

$$\tilde{w}^{(s)} = MG_{i-1}(\tilde{w}^{(s-1)}, g_{i-1}) \quad s = 1, 2, \dots, \gamma,$$

(A4) correction:

$$y^{(0)} = v^{(m_1)} + I_{i-1}^i \tilde{w}^{(\gamma)},$$

(A5) postsmoothing:

$$y^{(j)} = y^{(j-1)} + D_{i,j}^{POST}(g_i - A_i y^{(j-1)}), \quad j = 1, 2, \dots, m_2.$$

Finally, set  $w_i^{(1)} = y^{(m_2)}$ .

We shall now describe the evolution of the error within one call of  $MG_i$ . Given the problem  $A_i v_i = g_i$ , the initial guess  $w^{(0)}$ , we have

$$\begin{aligned} e^{(0)} &= v_i - w^{(0)} \\ e^{(1)} &= v_i - w^{(1)}, \quad w_i^{(1)} = MG_i(w_i^{(0)}, g_i). \end{aligned}$$

Define *error suppression operator*

$$B_i : e^{(0)} \mapsto e^{(1)}.$$

Denote

$$\begin{aligned} J_i^{PRE} &= (I - D_{i,m_1}^{PRE} A_i)(I - D_{i,m_1-1}^{PRE} A_i) \cdots (I - D_{i,1}^{PRE} A_i), \\ J_i^{POST} &= (I - D_{i,m_2}^{POST} A_i)(I - D_{i,m_2-1}^{POST} A_i) \cdots (I - D_{i,1}^{POST} A_i). \end{aligned}$$

In the previous part, we saw that the error after smoothing with  $D$  satisfies (in the previous notation)

$$\mathbf{e}^{(i+1)} = (I - DA)\mathbf{e}^{(i)}$$

and the error after coarse-space correction

$$\mathbf{e}^{(i+1)} = (I - I_0^1 A_0^{-1} R_1^0 A_1)\mathbf{e}^{(i)}.$$

Analogously, we get for two levels and  $MG_1$ ,

$$B_1 = J_1^{POST}(I - I_0^1 A_0^{-1} R_1^0 A_1)J_1^{PRE}.$$

How  $B_i$  looks on finer levels with  $i > 1$ ? The smoothing stays (up to the indices) the same and the difference shall be in the ‘‘coarse-space correction’’ part. We therefore expect

$$B_i = J_i^{POST} \boxed{\text{CP}} J_i^{PRE},$$

where  $\boxed{\text{CP}}$  stands for a recursive call of  $MG_{i-1}$  and most probably will involve the error suppression  $B_{i-1}$ .

Let now focus on development of the error in steps (A2)–(A4):

- after (A1) we have  $v^{(m_1)} \approx v_i$  with the error  $\sigma^{(m_1)} = v_i - v^{(m_1)}$ .
- In the restriction (A2)

$$g_{i-1} = R_i^{i-1} (g_i - A_i v^{(m_1)}) = R_i^{i-1} A_i \sigma^{(m_1)}.$$

- The coarse-space solve (A3) starts with zero initial guess, therefore the error is equal to the solution  $\tilde{w}^*$ . After one application of  $MG_{i-1}$  the error is  $B_{i-1}\tilde{w}^*$  and there holds

$$\tilde{w}^{(1)} = \tilde{w}^* - (\tilde{w}^* - \tilde{w}^{(s)}) = \tilde{w}^* - B_{i-1}\tilde{w}^*.$$

After  $\gamma$  steps of  $MG_{i-1}$  therefore

$$\tilde{w}^{(\gamma)} = (I - (B_{i-1})^\gamma)\tilde{w}^*.$$

- In the correction (A4)

$$y^{(0)} = v^{(m_1)} + I_{i-1}^i \tilde{w}^{(\gamma)}$$

and therefore

$$\begin{aligned} v_i - y^{(0)} &= (v_i - v^{(m_1)}) - I_{i-1}^i \tilde{w}^{(\gamma)} \\ &= \sigma^{(m_1)} - I_{i-1}^i (I - (B_{i-1})^\gamma)\tilde{w}^* \\ &= (I - I_{i-1}^i (I - (B_{i-1})^\gamma) A_{i-1}^{-1} R_i^{i-1} A_i) \sigma^{(m_1)} \end{aligned}$$

Altogether, the error suppression operator is

$$B_i = J_i^{POST} (I - I_{i-1}^i (I - (B_{i-1})^\gamma) A_{i-1}^{-1} R_i^{i-1} A_i) J_i^{PRE}, \quad B_0 = 0. \quad (2.1)$$

If the operators  $A_i$ ,  $R_i^{i-1}$ ,  $I_{i-1}^i$ ,  $D_{i,\ell}^{PRE}$ ,  $D_{i,j}^{POST}$  are linear, so is  $B_i$ . Additionally,  $B_i$  is independent of  $g_i$  or  $w_0$ .

To prove the convergence of the multigrid, it is sufficient show that

$$\rho(B_i) < 1.$$

Since for every (induced) matrix norm  $\rho(B_i) \leq |||B_i|||$ , we show that

$$|||B_i||| < 1 - \epsilon, \quad \epsilon > 0,$$

for some appropriate norm.

To sum up,

$$|||B_i||| < 1 \implies \rho(B_i) < 1 \implies (B_i)^j e^{(0)} \rightarrow 0 \quad \forall w_0, g_i.$$

## 2.2 Convergence of a symmetric multigrid

A symmetric multigrid is an important variant of multilevel methods. In particular, it can be used as a preconditioner for the Conjugate Gradient method.

The symmetry in MG is represented by these assumptions:

- (S1) operators  $A_i$  are self-adjoint and positive definite (in case of matrices,  $A_i$  are symmetric positive-definite),
- (S2)  $I_{i-1}^i = (R_i^{i-1})^*$  in the sense of inner products  $(\cdot, \cdot)_i$  on  $M_i$ ,
- (S3)  $J_i^{PRE} = (J_i^{POST})^*$ ,
- (S4) variational property  $A_{i-1} = R_i^{i-1} A_i I_{i-1}^i$ ,
- (S5)  $J_i^{PRE} A_i = A_i J_i^{PRE}$  (which also assures that  $(J_i^{PRE})^* A_i = A_i (J_i^{PRE})^*$ ).

Thanks to (S1), operators  $A_i$  define inner products and the norm

$$\begin{aligned} (u, v)_{A_i} &= (A_i u, v)_i & u, v \in M_i \\ \|u\|_{A_i} &= (u, u)_{A_i}^{1/2} & u \in M_i \end{aligned}$$

We also define an operator of (exact) coarse-space correction  $Q_i : u \rightarrow w$  such that

$$w = u - I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i u.$$

Therefore

$$Q_i = I - I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i.$$

**Lemma 2.1** (Properties of  $Q_i$ ). *Under conditions (S1), (S2), (S4) the operator  $Q_i$  is self-adjoint projector from  $M_i$  into orthogonal complement of  $I_{i-1}^i M_{i-1}$  with respect to the inner product  $(\cdot, \cdot)_{A_i}$ .*

*Proof.* Let  $w = Q_i u$ . We show that

$$(w, z)_{A_i} = 0 \quad \forall z \in I_{i-1}^i M_{i-1}.$$

We have

$$\begin{aligned} (A_i w, z)_i &= (A_i Q_i u, z)_i \stackrel{z=I_{i-1}^i y}{=} (A_i Q_i u, I_{i-1}^i y)_i \\ &= (u, A_i I_{i-1}^i y)_i - \underbrace{(R_i^{i-1} A_i I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i u, y)_i}_{A_{i-1}} \\ &= (R_i^{i-1} A_i u, y)_i - (R_i^{i-1} A_i u, y)_i = 0. \end{aligned}$$

Operator  $Q_i$  is a projection (as we have already seen)

$$Q_i^2 = I - 2I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i + I_{i-1}^i A_{i-1}^{-1} \underbrace{R_i^{i-1} A_i I_{i-1}^i}_{A_{i-1}} A_{i-1}^{-1} R_i^{i-1} A_i = I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i.$$

Finally,  $Q_i$  is self-adjoint because

$$\begin{aligned} (Q_i u, v)_{A_i} &= (A_i (I - I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i) u, v)_i \\ &= (A_i u, v)_i - (A_i u, I_{i-1}^i A_{i-1}^{-1} R_i^{i-1} A_i v)_i = (u, Q_i v)_{A_i}. \end{aligned}$$

□

Now we can state a sufficient condition for the convergence. Let there exist  $c^* > 0$  such that  $\forall i = 1, \dots, k$ , and  $\forall v \in M_i$

$$\|v\|_{A_i}^2 - \|J_i v\|_{A_i}^2 \geq c^* \|Q_i J_i v\|_{A_i}^2. \quad (2.2)$$

After the first, introductory part of the course, we should be able to properly understand the condition (2.2). We can discuss two scenarios. First, the vector  $v$  is “oscillatory” so that it can be efficiently reduced by smoothing giving  $J_i v$  with small norm. In that case, the coarse-space correction of  $J_i v$  (giving the vector  $Q_i J_i v$ ) need not be very efficient. Second case is a smooth vector that is not smoothed out and therefore  $\|v\|_{A_i}$  and  $\|J_i v\|_{A_i}$  are close to each other. Therefore, to fulfill (2.2), the vector  $Q_i J_i v$  after the coarse-space correction must be significantly reduced.

**Theorem 2.2** (Convergence of a symmetric V-cycle MG). *Let (S1) – (S5) hold together with (2.2) for  $MG_i$  algorithm with  $\gamma = 1$ . Then*

$$\|B_i\|_{A_i} = \sup_{v \in M_i \setminus \{0\}} \frac{\|B_i v\|_{A_i}}{\|v\|_{A_i}} \leq \frac{1}{1 + c^*} (< 1). \quad (2.3)$$

*Proof.* Will be given on the lecture. Otherwise see [Shaidurov, 1995, Thm. 4.5].  $\square$

A single inequality (2.2) yielding a sufficient condition for convergence is presented in [Shaidurov, 1995, Eq. (4.82)] probably for the first time. More common in the literature is to have two conditions, one for the intergrid operators and the second for the smoother. We now state these conditions and show that they together imply (2.2) and, consequently, the convergence of the multigrid.

First, consider so-called *approximation assumption*: let there exist constant  $c_1 > 0$  such that

$$(Q_i v, v)_{A_i} \leq c_1 \frac{\|A_i v\|_i^2}{\lambda_i^*} \quad \forall v \in M_i, \quad (2.4)$$

where  $\lambda_i^*$  is either the largest eigenvalue of  $A_i$  or its upper bound.

Second, *smoothing assumption* states: let there exist  $c_2 > 0$  such that

$$\frac{\|A_i J_i v\|_i^2}{\lambda_i^*} \leq c_2 (\|v\|_{A-i}^2 - \|J_i v\|_{A-i}^2), \quad \forall v \in M_i. \quad (2.5)$$

**Lemma 2.3.** *Under conditions (S1), (S2), (S4) the assumptions (2.4) and (2.5) imply (2.2) with the constant  $c^* = (c_1 c_2)^{-1}$ .*

*Proof.* From Theorem 2.1,  $Q_i$  is a projection and self-adjoint with respect to  $(\cdot, \cdot)_{A_i}$ . Therefore

$$\|Q_i v\|_{A_i}^2 = (Q_i v, Q_i v)_{A_i} = (Q_i^2 v, v)_{A_i} = (Q_i v, v)_{A_i}.$$

Now choose  $J_i v$  for  $v$ , giving

$$\|Q_i J_i v\|_{A_i}^2 = (Q_i J_i v, J_i v)_{A_i} \stackrel{(2.4)}{\leq} c_1 \frac{\|A_i J_i v\|_i^2}{\lambda_i^*} \stackrel{(2.5)}{\leq} c_1 c_2 (\|v\|_{A_i}^2 - \|J_i v\|_{A_i}^2),$$

which gives (2.2).  $\square$

## 2.2.1 Smoothing assumption and stationary iterative solvers

DOPLNIT

## 2.3 Convergence in a general case

In a general case, we assume

(G1)  $A_i$  are nonsingular,  $i = 0, 1, \dots, k$ ,

(G2)  $I_{i-1}^1 = (R_i^{i-1})^*$ ,

(G3)  $\|J_i\|_i \leq c_3$ ,  $i = 1, 2, \dots, k$ ,

(G4)  $\underline{c}_I \|I_{i-1}^1 u\|_i \leq \|u\|_i \leq \bar{c}_I \|I_{i-1}^1 u\|_i, \forall u \in M_i, i = 1, 2, \dots, k,$

(G5) the number of smoothing steps is  $m = m_1, m_2 = 0,$  and

$$\|A_i^{-1} - I_{i-1}^1 A_{i-1}^{-1} R_i^{i-1}\|_i \cdot \|A_i J_i\|_i \leq \eta(m), \quad i = 1, \dots, k,$$

where  $\eta$  does not depend on  $i$  and converges to 0 for  $m \rightarrow \infty.$

The assumption (G5) can be replaced by

$$(G5a) \quad \|(A_i^{-1} - I_{i-1}^1 A_{i-1}^{-1} R_i^{i-1}) A_i J_i\|_i \leq \eta(m), \quad i = 1, \dots, k.$$

In a general case, there is no norm induced by  $A_i$  so that we will work with the norm

$$\|u\|_i = (u, u)_i^{1/2}, \quad u \in M_i, \quad i = 0, 1, \dots, k.$$

The associated operator norm is

$$\|A\|_i = \sup_{u \in M_i \setminus \{0\}} \frac{\|Au\|_i}{\|u\|_i}.$$

**Theorem 2.4** (Convergence of W-cycle in the general case). *Under (G1)–(G5) (alternatively (G5a)) for  $MG_i$  algorithm with  $\gamma = 2, m_1 = m,$  and  $m_2 = 0.$  Then for arbitrary  $\xi \in (0, 1)$  there exists  $m_0$  such that  $\forall m \geq m_0$*

$$\|B_i\|_i \leq \xi \quad \forall i = 0, 1, \dots, k. \quad (2.6)$$

*Proof.* Will be given on the lecture. Otherwise see [Shaidurov, 1995, Thm. 4.11].  $\square$
